Scientific Justification *Limited to 1 page of text plus 2 pages for figures and references.*

Executive Summary: We propose a high-cadence DECam imaging program to measure optical variability in a sample of dwarf galaxy active galactic nuclei (AGN) hosting intermediate-mass black hole (IMBH) candidates. These systems provide critical constraints on black hole seed formation and the occupation fraction of black holes in low-mass galaxies, yet their variability properties remain largely unexplored. Using a sample of 229 spectroscopically identified dwarf galaxy AGN candidates from SDSS, we select a subset of 11 dwarf galaxies within 5 DECam fields. We propose observations in g and r bands with a cadence of 7 exposures per week over a 10 week baseline, enabling sensitivity to variability on days–to-weeks timescales. Exposure times are chosen based on DECam Exposure Time Calculator (ETC) estimates to achieve high signal-to-noise, resulting in ∼10s (r) and ∼15s (g) exposures (+ 30s overheads). The total requested time is ∼8.5 hours. This program will (1) measure the variability fraction of IMBH AGNs, (2) characterize variability amplitudes as a function of black hole mass and accretion rate, and (3) test the ability of multi-band variability to distinguish AGNs from transient contaminants. The results will provide the first systematic constraints on short-timescale variability in low-mass AGNs and establish variability as a robust tool for confirming IMBH candidates.

Motivation: Active galactic nuclei (AGN) in dwarf galaxies provide a crucial probe of black hole seed formation and the occupation fraction of black holes in low-mass systems (Reines & Comastri 2016; Greene et al. 2020). Intermediate-mass black holes (IMBHs; $\sim 10^4$–$10^6\,M_\odot$) are particularly important in this context, yet their demographics and accretion properties remain poorly constrained.

Spectroscopic surveys have identified candidate IMBH AGNs through broad emission lines (Greene & Ho 2007; Baldassare et al. 2015, 2017), as well as through emission line diagnostics in dwarf galaxies (Reines et al. 2013). However, these methods can suffer from contamination by star formation or transient phenomena, and independent confirmation of AGN activity is often required.

Optical variability provides a powerful and independent diagnostic of accretion onto black holes. Time-domain surveys have demonstrated that variability selection can robustly identify AGNs and characterize their stochastic behavior (e.g., Akiyama et al. 2018; Tachibana et al. 2020, Burke et al. 2021). However, these studies focus primarily on variability-selected samples rather than spectroscopically identified IMBH AGNs. As a result, the variability fraction and scaling relations for low-mass AGNs are particularly on short (day-to-weeks) timescales where low-mass systems are expected to vary more rapidly.

We propose a high-cadence, multi-epoch imaging program to measure optical variability in a sample of dwarf galaxy hosting spectroscopically identified IMBHs candidates. Our program addresses two key objectives: (1) determine whether spectroscopically identified IMBH AGN candidates exhibit variability on days–weeks timescales and (2) whether multi-band variability can distinguish AGNs from contaminating transients such as supernovae. Due to our limited sample containing only 11 objects, we will explore tests for any preliminary trends between black hole mass and Eddington ratio with variability.

The proposed observations will provide systematic constraints on short-timescale variability in spectroscopically identified IMBH AGNs and establish variability as a robust diagnostic for confirming low-mass AGN candidates.

Science Goals:

1. Do spectroscopically-identified broad-line IMBH AGN candidates often exhibit optical variability on days-to-weeks timescales?

2. Can photometric variability surveys distinguish broad-line AGNs from transient interlopers (i.e., SNe)?

Table 1: Finalized subsample of 11 targets from Greene & Ho 2007 sample of 229 IMBH AGN candidates. Column (1) lists the target identifier in J2000 coordinates. Columns (2) and (3) give the right ascension and declination in degrees. Column (4) provides the spectroscopic redshift, (z). Columns (5) and (6) list the apparent magnitudes in the SDSS (g)- and (r)-bands, respectively. Column (7) gives the logarithm of the black hole mass in solar units, ($\log(M_{\rm BH}/M_\odot)$). Column (8) lists the logarithm of the bolometric-to-Eddington luminosity ratio, ($\log(L_{\rm bol}/L_{\rm Edd})$).

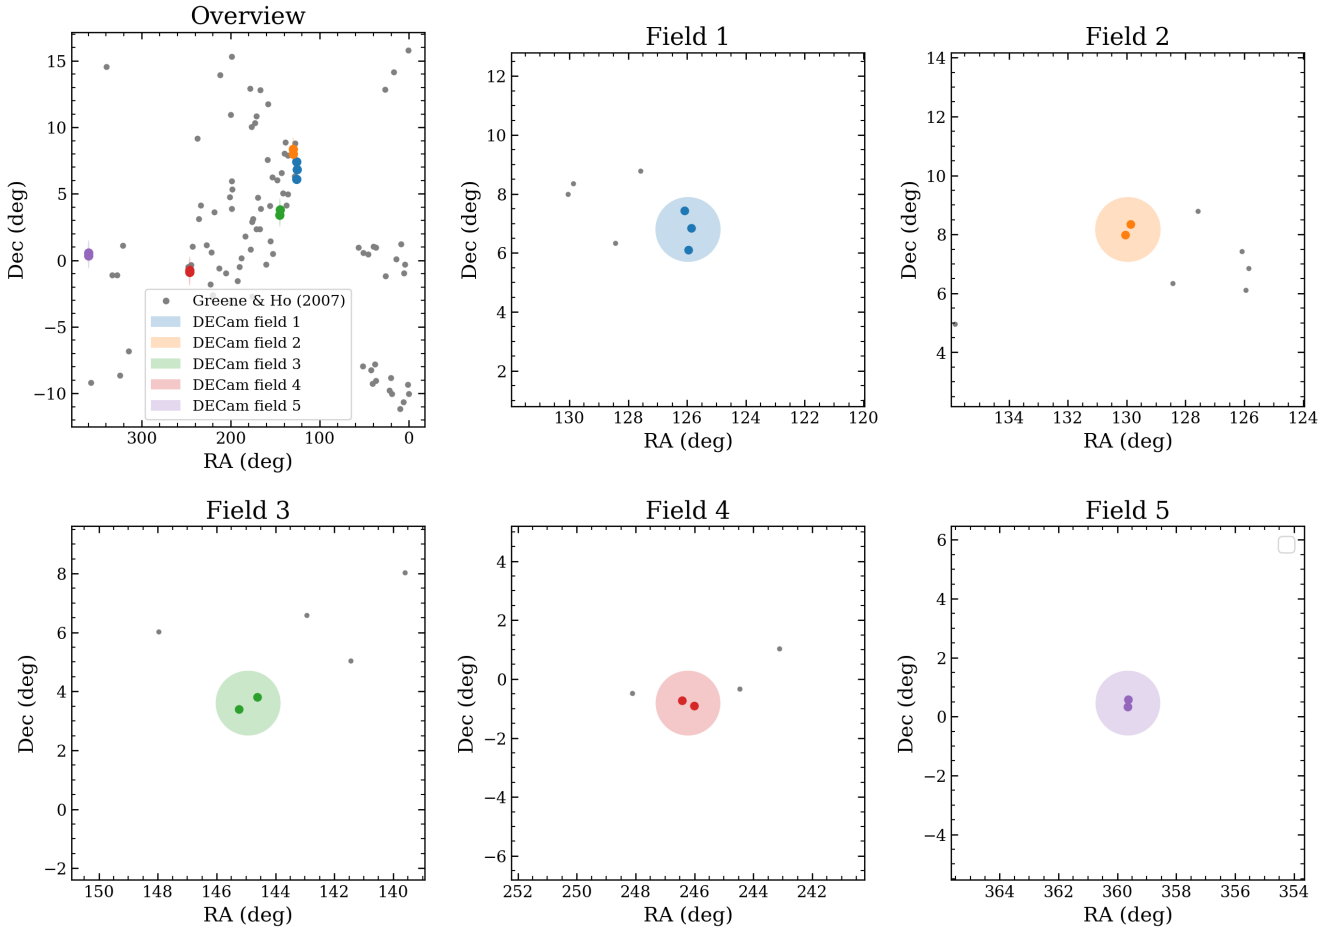

Figure 1: Spatial distribution of the target sample and selected DECam pointings. The top-left panel shows the full sample (gray points), with targets assigned to each DECam field highlighted in distinct colors. The shaded regions indicate the approximate DECam field of view (radius $\approx 1.1^\circ$) for each pointing. The remaining panels show zoomed-in views of each individual field, illustrating the coverage of targets within a single DECam footprint. Axes are given in right ascension (RA) and declination (Dec) (J2000).

Experimental Design *Limited to 1 page of text*

Sample Selection

Our targets are drawn from the spectroscopically identified sample of low-mass, broad-line AGN candidates presented in Greene & Ho (2007), which provides one of the most well-characterized catalogs of intermediate-mass black hole candidates in the local universe. This sample is particularly well suited to our study, as the presence of broad emission lines provides strong evidence for active accretion and allows for reliable black hole mass estimates.

From this parent sample, we apply selection cuts of $z \leq 0.2$ and $r \leq 20$ to ensure that targets are both nearby and sufficiently bright for high-cadence photometric monitoring with the Dark Energy Camera (DECam). We further restrict the sample to objects observable from CTIO, removing sources at declinations inaccessible from the Blanco 4-m telescope.

Due to the wide sky distribution of the parent sample (Greene & Ho 2007), we then select targets that can be grouped into common DECam pointings to maximize observational efficiency. This results in a final sample of 11 targets distributed across 5 DECam fields. Although reduced in size, this subset retains the defining characteristics of the parent IMBH AGN population and is well suited for a focused pilot study of short-timescale optical variability.

Observing Strategy

The goal of our proposed program is to test whether spectroscopically identified, low-mass AGN candidates exhibit measurable optical variability on day-to-week timescales. Imaging photometry provides a highly efficient avenue for monitoring variability across a wide field of view (FOV), enabling simultaneous observations of multiple targets within a single pointing. Compared to spectroscopy, photometric observations require significantly less exposure time per target and allow repeated visits over large samples, making them ideal for time-domain studies. The wide FOV of DECam (~ 3 deg^2) allows us to monitor many targets simultaneously within a single pointing. We will obtain multi-epoch photometry in both the g- and r- bands, using the r-band as the primary variability tracer and the g-band to provide color information that can help distinguish AGN-like variability from transient contamination.

We adopted a photometric precision target of $\sim$0.03 mag, corresponding to S/N $\gtrsim 40$ for our dimmest targets (mag ~ 20). This is sufficient to detect low-amplitude variability while remaining consistent with the precision regime demonstrated by Stripe 82 photometry (Sesar et al. 2007).

We adopt a daily cadence (7 times per week) on a 10-week baseline. AGN optical variability timescales are known to correlate with black hole mass, with lower-mass systems exhibiting more rapid variability (e.g., Kelly et al. 2009; MacLeod et al. 2010; Burke et al. 2021). Extrapolating these relations to the mass range of our sample ($\log(M_{\rm BH}) \sim 5.4 - 6.3$) implies characteristic variability timescales of order $\sim$10–40 days, consistent with observations of low-mass AGN such as NGC 4395, which shows variability on timescales of days to weeks. The program is designed as a pilot study; with only 11 targets, repeated observations over multiple epochs will allow us to measure variability amplitudes, compare behavior across bands, and determine whether these low-mass nuclei are consistent with stochastic AGN variability or with transient-like evolution. Additionally, with DECam's large FOV we can search for additional variable sources within the DECam fields, increasing the scientific return of the program.

Technical Description *Limited to 1 page of text*

The observations will be carried out with DECam on the CTIO Blanco 4-m telescope. DECam is well suited to this program because its wide field of view allows multiple targets to be monitored simultaneously within each pointing, making it efficient for time-domain work on a sparse but sky-localized dwarf galaxy AGN sample. The final sample requires 5 DECam fields to cover the 11 selected targets.

Observations will be obtained in both the g and r bands. Based on DECam Exposure Time Calculator (ETC) calculations, we adopt exposure times of 15s in the g-band and 10s in r-band for the representative targets in the sample. These exposure times will provide an adequate signal-to-noise ratio (≥ 40) for variability measurements while optimizing the balance between depth and cadence. We used ETC values derived for our dimmest object in either band, which in our case is a magnitude of $\sim$20 for both g- and r- bands. Additionally, in our ETC calculations we adopted typical conditions at CTIO, with seeing of approximately 1" and airmass less than 1.5. Lastly, exposure times were calculated assuming full-moon conditions, providing a conservative estimate that ensures the required signal-to-noise ratio can be achieved under all sky brightness conditions.

DECam overheads must be included separately from the exposure time estimations from the ETC. For each exposure, we adopt an overhead of approximately 30 seconds, which includes CCD readout and filter/telescope transitions. Thus, the effective time per exposure is approximately 40s in r and 45s in g. The total program time is therefore determined by the number of fields, filters, and visits across the entire baseline. For a 5-field program observed 7 times per week (daily) over $\sim$10 weeks in both filters. We request a total of 8.5 hours of DECam time distributed over a 10-week baseline.

The observations will yield multi-epoch light curves in both filters for all 11 targets. The resulting exposures from our program will be used to measure flux variability, assess band-to-band behavior, and evaluate whether the targets show AGN-like stochastic variability or transient-like changes. The combination of wide-field imaging, short exposures, and repeated visits makes DECam an efficient and technically well-matched instrument for this experiment.
